#### Abstract

In this work studies on mass burn rate of spheres with six different species of 10, 15 and 20 mm diameter, with some species at various initial temperatures below pyrolysis conditions, namely, 300, 373, 393 and 423 K have been conducted to examine the possibility of determining the heat of pyrolysis and so the transfer number, B for biomass species. Ficus, Pine, Acacia, Ivory, Tamarind and Balsa with density variation from 250 to 950 kg/m<sup>3</sup> and at moisture fractions of 0 to 0.12, with four of them at different initial temperatures were experimentally studied to help determine the constants in a burn rate correlation developed using scaling laws. In respect of the initial temperature effect, the increase in the mass burn rate is up to 25 % and in respect of increase in moisture fraction, the mass burn rate decrease is by a maximum of 25 %. The data of more than 90 experiments are used in a model based on scaling laws to extract the heat of pyrolysis and so, the transfer number, B and match the the mass burn rate data. The key parameter affecting B is the heat of pyrolysis (or phase change) that is taken to be different for different species. The predictions from the model compare with experiments to within a mean square error of 5 %. The experiments are also performed with the cylinders of diameter 10 and 15 mm and cubes of 10 mm to examine the differences in the combustion process and whether they offer better solution for the extraction of the heat of pyrolysis.

The burn rate correlation has been developed for spheres and extended to other geometries like cylinders of circular and square cross section using the square root of the surface area as the characteristic dimension. The results from the present correlation are compared with the present experiments and those of earlier studies. Also, the data on conversion in biomass pyrolysis have been examined in the light of the present correlation and the validity of the correlation in such cases is discussed.

## 0.1 Introduction

Three motivations have led to the extensive study of thermo-chemical conversion of biomass. When used as a source of energy, the design of the gasification or combustion system requires an understanding the burn behaviour as influenced by its density, shape, size and moisture effects. When used as an infrastructure in buildings, the interest is to see how to avoid unintended fires or minimize the ill-effect due to one of the parameters as above, noting that there is no control on the choice since they are already fixed in the infrastructure. The third motivation is to study product distribution in pyrolytic conditions to enable obtain biochar of a desired specification. In the first one, enhancement of combustion is achieved through the use of forced convection of air. In the second one, estimates have to be made of the heat transfer by radiation from adjoining fires or heated surfaces and the heat release of reacting pyrolysed solid material with air induced by free convection. In the third one, detailed chemical and structural analysis are performed on relatively small samples using radiant heat flux and track the product distribution. The condensed phase processes are similar. Heat absorption by conduction to a temperature at which condition pyrolysis becomes significant is a key feature. The heating rates are large in the case of combustion process. The heating rates in the case of fires vary from small to large and simulation of this is performed through the use of radiant sources like in a cone calorimeter. In the third case, the radiation flux is set as a part of the experiment. Studies on the fundamentals of the process - combustion or fire - have been made for over six decades.

Experiments on the burn behaviour of wood of cubical and rectangular geometries have been made by some researchers. Bartlett et al (2018) in their review of the burning behaviour of wood have described all the phases of the combustion process and have provided the data from earlier work. Observations on the burn rate effects of density and moisture from the data suggest a possible overlap, a feature remedied by Friquin (2011) as he brought out the density effects on charring rates under irradiated conditions. Tinney (1965), Capart et al (1988), de Ris et al (1973) have examined pyrolysis and combustion behaviour of cylinders of wood at ambient and higher pressures with and without flow of nitrogen or depending on whether pyrolysis or combustion is to be simulated. Maa and Bailie (1973) have conducted a modeling study delineating the regimes of diffusion dominated and reaction dominated behavior. Increase in sample radius beyond 30 mm is stated to be diffusion controlled and less than 1 mm reaction controlled. The intermediate regime is covered by the combined role of both chemical kinetics and diffusion. Pyle and Zaror (1984) have progressed the understanding by identifying the regimes of conversion behavior based on Biot number and pyrolysis number. The pyrolysis number is the ratio of condensed phase chemical kinetic time to conduction time. They performed experiments on 6, 15 and 22 mm diameter cylinders with lengths between 60 to 90 mm and obtained the mass loss and conversion times at furnace temperatures between 640 and 780 K. Lu et al (2008, 2010) have presented a study of the combustion of single particles.

Blackshear and Murty (1965) performed experiments on cylindrical cellulosic samples and measured the mass loss and temperatures of samples at various radii. The measured temperature time histories with the DTA values were interpreted to infer that the decomposition of the samples takes place endothermically at temperatures of 300 - 400°C and exothermically above 500°C. Also, they have tried to extract the mass transfer number B for the solid fuel by deploying the method similar to that for methanol fuel and inferred its value as 1.5. Orloff and de Ris (1971) also remark that the transfer number of biomass as 1.5 without any qualifying observations. The transfer number is defined as follows:

$$B = \frac{c_{pg}(T_f - T_s)}{[H_p + c_{pf}(T_s - T_{ini})]}$$
(1)

where  $c_{pg}$  is the gas phase specific heat,  $T_f$  and  $T_s$  are the flame (or gas phase) and surface temperatures,  $H_p$  is the heat of pyrolysis,  $c_{pf}$  is the specific heat of the fuel and  $T_{ini}$  is the initial fuel temperature. Just as for liquid fuels where these properties depend on the specific fuel, it should be expected that these values should depend on the specific biomass and the value of B = 1.5can at best be treated as an indicative value. Two key parameters,  $c_{pf}$  and  $H_p$ that affect B have been explored in the literature. Ragland and Aertis (1991) have presented the broad parameters for several thermal properties based on earlier data. Specific heat increases with initial temperature and moisture content with values varying from 1.3 to about 2 kJ/kg K. More recent studies by DuPont et al (2014) have shown that the specific heat is nearly the same for more than 20 species that they studied and hence confirmed the conclusions of Ragland and Aertis (1991). Also, Radmanivic et al (2014) have presented a review indicating similar results over a different range of biomass.

In so far as heat of pyrolysis is concerned, there has been much debate in the literature. Roberts (1971a, 1971b) has indicated the issues related to  $H_p$ . A discussion on the paper (Roberts, 1971b) by Kanury Murty keeps the matter related to exothermicity or otherwise of the pyrolysis process unsettled. Later, Milosavljevic et al (1996) have summarized the values of  $H_p$  by different researchers over a time and the range of values is from -2100 kJ/kg to +2500 kJ/kg on the basis of mass of volatiles, the negative sign representing exothermicity. The results from several researchers have been re-examined by others providing qualitatively different values for the heat of pyrolysis. For instance, the reported values of Roberts and Clough (1963) as -314 to -1700 kJ/kg has been modified by Kung and Kalekar (1973) using a more refined calculation procedure as +203 kJ/kg. What is more, the basis of most of these results is the amount of volatiles which in itself is another parameter that could vary between 0.5 to 0.8 of the mass of the solid fuel depending essentially on the heating rate adopted in the studies. As such, one can recognize that the uncertainty in the values of  $H_p$  arising out of these studies is wide.

One classical argument that since the burn rate,  $\dot{m}$  depends on B through ln(1 + B), larger changes in B will not influence the estimate of burn rate significantly leaves the question of determination of B for biomass uninteresting for resolution and therefore the question has remained open. We can estimate the sensible enthalpy of the biomass as it heats up from 300 K up to the pyrolysis temperature, say, 600 K for the choice of  $c_{pf}$  of 1.5 kJ/kg K as 450 kJ/kg. If the gas phase enthalpy change =  $c_{pg}(T_f - T_s)$  which is the numerator in the equation for B is estimated as = 1 x (1300 - 600) = 700 kJ/kg and the transfer number, B is taken as 1.5, the value of  $H_p$  will have to be + 16 kJ/kg (endothermic). This range appears small considering the range of values set out in Milosavljevic et al (1996). If the value of  $H_p$  is say 100 kJ/kg, B = 1.27 and if it is - 100 kJ/kg, B = 2. The change in burn rate which is proportional to ln(1+B) will be by a factor of 1.34 between the  $H_p$  values of -100 to 100 kJ/kg. This change is not small considering the fact that the  $H_p$  values have a wide range of uncertainty.

Roberts (1971a) presented arguments indicating that the process of pyrolysis in wood can be understood to be composed of that of its constituents – largely of cellulose and lignin with cellulose showing much smaller exothermicity than lignin. Additional arguments are made to indicate that the structure of wood also has influence on the heat of pyrolysis. What appears as a significant outcome of this work is that the biomass composition that would include extractives and crude protein can all influence the pyrolysis process. This allows for the possibility of the value of B for biomass to be dependent on the composition even if such a dependence may not be very strong.

A few studies have been completed on the combustion of cubes and spheres of biomass. Huff (1982) conducted experiments on cubes 5 mm to 20 mm in size made of of balsa, pine and oak. The process is conducted in a furnace maintained at various test temperatures, 797, 1963 and 1345 K. The plot of the burn time as a function of the size is the test data. Because the experiments have heat transfer from the furnace also and also the process of ignition of larger size cubes can take time, the data reduction to derive fundamental information requires further analysis. Kuo and Hwang (2003) conducted experiments with rosewood spheres of 20 mm and 50 mm diameter in air streams at 673 and 773 K at Reynolds numbers of 250 to 1000. The process of ignition was tracked and related to in-depth conduction parameters. The burn rate data from these studies seem so deeply connected to the ignition process that the starting condition for combustion is different for various cases making it difficult to draw more fundamental inferences. For instance, for the same 20 mm diameter sphere at the same furnace temperature of 773 K, the samples are ignited by the flow of hot air and so, the combustion process is coupled with the ignition process which varies with the Reynolds number. For instance, the burn flux changes from 8.6 to  $10.7 \text{ g/m}^2\text{s}$  with change in Reynolds number from 208 to 346. The sample undergoing combustion at 773 K is at different levels preparation in terms of loss of volatiles and hence the combustion process cannot be treated identical. Nevertheless, the observed maximum burn flux obtained around the point of ignition or the beginning of flaming combustion and are in the range of 10 g/m<sup>2</sup>s to 18 g/m<sup>2</sup>s depending on the size of wood sphere and heating conditions.

Mukunda et al (1984) conducted experiments on teak wood spheres, 10 to 25 mm diameter and stated a result for the burn rate as follows.

$$\dot{m} = 7 \times 10^{-4} d_s \tag{2}$$

with  $\dot{m}$  in kg/s and  $d_s$  in m. The scaling of mass burn rate with  $d_s$  has been brought out from this study. This result can also be expressed as

$$\frac{t_b}{(\rho_{fu}/650)} = 50 \left[\frac{d_s}{10}\right]^2 \tag{3}$$

where the biomass density,  $\rho_{fu}$  is in kg/m<sup>3</sup> and the diameter of the wood sphere,  $d_s$  is in mm. This result is an average behavior of the data since their experimental data show a 30 % increase in  $\dot{m}/d_s$  with the diameter increasing from 10 to 25 mm. The analysis performed that accounts for free convective transfer using standard correlation based on the experimental data of Agoston et al (1957) shows that increase in  $\dot{m}/d_s$  over the diameter range of about 30 %. Interestingly, Agoston et al (1957) are the only authors to have done experiments on liquid fuels at large diameters to enable extracting the data for free convective effects. Their work was on spheres of 3.15, 6.35, 9.51 and 13.2 mm diameter (comparable to the size of wood spheres) made of porous alundum that was fed by the liquid fuel by a short, stainless-steel, hypodermic-tubing feed line such that the surface of the sphere is just wet. These results are considered in the present study.

#### 0.2 The basis of the present approach

In view of the discussion above, it appears that a new approach needs to be developed to estimate B. It is first to be noted that mass burn rate is the most important outcome of such studies and relevant for the design of combustion and fire safety situations. It is considered important to use a simple geometry for tests and analysis.

In order to design experiments to extract B, we start with the basic mass burn rate expression for a fuel sphere as

$$\dot{m}_n = \dot{m}/C_\mu d_s \tag{4}$$

$$= ln(1+B)f(Gr,Si_d)$$
(5)

$$C_{\mu} = 2\pi(\mu_g/Pr) \tag{6}$$

$$B = c_{pg}(T_f - T_s) / [H_p + c_{pf}(T_s - T_{ini})]$$
(7)

where  $\dot{m}_n$  is the dimensionless mass burn rate,  $d_s$  is the sphere diameter,  $C_{\mu}$  is a constant depending on the chosen values of  $\mu_g$ , the representative gas phase viscosity and the Prandtl number, Pr,  $f(Gr, Si_d)$  is the function of Grashof number, Gr to address convective effects and  $Si_d$ , the change in diameter of the biomass due to shrinkage during volatilization. The above expression without  $Si_d$  is the standard burn rate expression valid for liquid droplets and also for solid spheres with little change in size.

It was brought out earlier that the denominator of *B* has  $c_{pf}(T_s - T_{ini})$  which is significant, amounting to 450 kJ/kg at  $T_{ini}$  of 300 K. The aim is to study how the biomass burn rate varies if  $T_{ini}$  is increased to as high values

as possible so that the sensible enthalpy part can be reduced. Typically,  $T_s$  is about 600 K and various DTA/TGA studies suggest that decomposition begins at around 473 K. Thus, the maximum value of  $T_{ini}$  will be 473 K. By conditioning the biomass spheres at various higher temperatures, the condensed phase enthalpy term can be brought down and perhaps, this would increase B. The word *perhaps* is used because it is not clear if  $H_p$  remains the same. The approach chosen here is to conduct experiments on the determination of burn characteristics of several species at various conditions that will affect the transfer number B significantly. The parameters under control are the moisture content that is intended to be varied up to sun-dry conditions (up to 12 %) on the one side and heat it to obtain 0 % moisture at ambient temperature and raise biomass conditioning temperature to 473 K in steps. The process of determining  $H_p$  and therefore B would be to seek good comparison of the above model with a wide range of data as wide as possible. More discussion on this follows.

Now we consider the expression related to Gr in the above equation. The Grashof number is defined by

$$Gr = \left[g[(T_f - T_{ini})/T_{ini}]d_s^3/(\mu_g/\rho_g)^2\right]$$
(8)

The choice of values for  $\mu_g$  and  $\rho_g$  are important to obtain predictions without an arbitrary constant. This choice is based on earlier work by Mukunda (1988) and Raghunandan and Mukunda (1977) where it has been shown that the variation of properties through the diffusion flame is very significant and the better representation of the properties will be those that are close to the flame. For liquid drops, the values of  $C_{\mu}$  works out to  $7 \times 10^{-4}$  kg/m s. With other values for the parameters, g = 9.81 m/s<sup>2</sup>,  $T_f$  = 1200 K,  $T_{ini}$  = 300 K,  $\mu_g$  = 6.6  $\times 10^{-5}$  kg/m s ,  $\rho_g$  = 0.4 kg/m<sup>3</sup>, we get  $Gr/d_s^3$  = 1.08  $\times 10^9$ .

Typical enhancement due to free convection is expressed as  $(1 + C_0Gr^n)$ . Earlier work by Agoston et al (1958) indicates that n = 0.3. The experimental data of Agoston et al (1957) is related to forced convection effects on the burn rate of larger drops. The data can be extrapolated back to zero forced convection to lead to free convection effects. These data are taken from their work and plotted against the drop diameter,  $d_s$ . Figure 1 shows such a plot. The variation is linear with respect to drop diameter indicating that the correction can be expressed as  $(1 + C_0Gr^{1/3})$ . The constant  $C_0$  works out to 0.035. The expression can be recast in terms of the diameter of the sphere, normalizing it with a diameter of 25 mm. The resulting correction due to free convection

Figure 1: Experimental results of Agoston et al (1957) and a curve fit

becomes  $(1 + 0.78d_s/25)$  with  $d_s$  expressed in mm. With this correction, the expression becomes

$$\dot{m}_n = ln(1+B) \left[ 1 + 0.78 \frac{d_s}{25} \right] f_1(Si_d)$$
 (9)

We now consider  $f_1(Si_d)$ , the effect of shrinkage. Much effort seems to have gone into developing detailed models and conducting experiments on the shrinkage effects in pyrolysis under the influence of radiant heat flux, the emphasis being on the product distribution (Barr et al, 2021, Di Blasi, 1996, Huang et al, 2014). Since the nature of biomass is very broad, the comparisons between predictions of detailed models and computation coupled with the assumptions of kinetics based on multi-step chemistry have remained quantitatively inadequate. This is so because the condensed phase chemistry is dependent on catalytic effects of inorganic ingredients drawn from the soil at the particular location where the tree is growing apart from inherent differences in the composition of cellulose, lignin and others. Precisely because of these reasons, it is unlikely that quantitative predictions will improve until a long time. Huang et al (2014) have provided some excellent photographic evidence of biomass shrinkage of 20 and 30 mm diameter spheres as they undergo thermal pyrolysis at temperatures of 673 to 973 K. Even though the pyrolysis process may not be completely representative of the phenomenon that occurs during combustion, the shrinkage values may actually be within the right order of magnitude. The results show a shrinkage of 12 to 15 % for a temperature of 673 K and at a duration of about 200 s typical of flaming combustion times of biomass considered here. The density of biomass  $(\rho_{fu})$ used in this experiment is 560 kg/m<sup>3</sup>. Even though the modeling effort on the biomass shrinkage has been extensive, there are no specific efforts to determine the role of density in the shrinkage process. Experimental evidence on teak wood sphere combustion (Mukunda et al, 1984) which has little dependence on chemistry in so far as burn rate behavior is concerned shows that by the end of flaming, there is a reduction in diameter of about 10 %. Thus we need to describe the shrinkage behavior during flaming to account for size changes in the burn rate behavior and the magnitude of the shrinkage being about 10 %. The effective mean value of shrinkage over the burn period is perhaps 6 to 7 %. The question of which overall parameter controls the shrinkage the most and based on earlier laboratory studies on wood of varying density, initial biomass density has been considered as the critical parameter in affecting the shrinkage with higher density leading to lower shrinkage The following equation was therefore set out.

$$f_1(Si_d) = 1 - 0.07 \ (650/\rho_{fu}) \tag{10}$$

where the fraction 0.07 was chosen based on the experimental value for teak with a density of 650 kg/m<sup>3</sup>. Typical densities considered in the present study vary from 250 to 950 kg/m<sup>3</sup>.  $f_1(Si_d)$  will vary between 0.82 to 0.95. Even though these values cause changes that are not significantly different from the accuracies of experiments (to with in  $\pm$  5 %), it was thought appropriate to include as systematic effect. The mass burn equation will now read as

$$\dot{m}_n = \ln(1+B) \left[ 1 + 0.78 \frac{d_s}{25} \right] \left[ 1 - 0.07 \frac{650}{\rho_{fu}} \right]$$
(11)

The third important parameter concerns B. Two biomass condensed phase parameters controlling the burn behavior are the specific heat and the heat of pyrolysis both of which have been discussed in the introduction. Based on these and the discussion to follow, the following expression for B is set out.

$$B = 1.0(1320 - 600) / [H_p + (1.5 + 4f_w)(600 - T_{ini})]$$
<sup>(12)</sup>

In the above equation,  $c_{pg}$  is set as 1.0 kJ/kg K,  $T_f$  is set as 1320 K (obtained from measurements discussed below) independent of  $f_w$  since the role of  $f_w$  is perceived partly to be chemical - the inefficiencies in the burning of more tarry compounds is compensated by less complex composition that emanates from the surface due to steam-char reactions, thus maintaining the flame temperature to be about same. The surface temperature,  $T_s$  is set at 600 K for all the situations considered. Its variation is about  $\pm$  20 K and is considered small enough to be ignored. The value of  $H_p$  is to be treated as a function of biomass. In order to provide a more general treatment and yet not too complex, it is taken as

$$H_p = H_{p0} + 50 \left[ (T_{ini} - 300)/300 \right]^2 + 100(f_w - 0.1)$$
(13)

The value of  $H_{p0}$  is the heat of pyrolysis of sun-dry biomass (considered as at  $f_w = 0.1$ ) at an ambient temperature of 300 K. It is the parameter that depends on the specific biomass. The choice of the values 50 and 100 in the above equation were those arrived at by varying them to provide minimum error in the predicted burn rate in comparison to a large number of experimental data on spheres to be described further. The only parameter specific to the biomass varied to get good fit for the entire range of tests is  $H_{p0}$ .

#### 0.2.1 Other geometries

An important question to answer would be the method of dealing with other geometries because several earlier studies have deployed cylinders with square or circular cross section with the length-to-lateral size ratio defined as the aspect ratio, AR which can vary from 1 to a large number. Classically, when AR = 1 (which translates to a cube in the case of square cross section), one invokes equivalent diameter based on the equality of volume. When AR is much larger than 1, it is unclear if the same idea would work. After a study, it is concluded that the surface area equivalence is what is appropriate and so, the dimension,  $d_{ch}$  is obtained from

$$d_{ch} = \sqrt{A_s/\pi} \tag{14}$$

It can be seen that for a sphere,  $d_{ch}$  translates to the diameter of the sphere,  $d_s$ . For cylinders with square cross section and circular cross section, we get

$$d_{ch} = d_{cy}\sqrt{(0.5 + AR)}$$
 (15)

$$= b\sqrt{4(0.5 + AR)/\pi}$$
 (16)

where  $d_{cy}$  is the diameter of a cylinder and b is the side of a square and AR is the length-to-lateral size ratio. Predictions and experimental data on the burn behavior of circular cylinders and cubes from other sources will be dealt with later in this paper.

#### 0.3 The experiments

Six different biomass were used in this study. Ficus (Ficus Benghalensis, banyan tree of India), Ivory (Wrightia tinctoria, locally called Haale tree), Acacia (Acacia nilotica, called babul locally), Pine (Pinus roxburghii), Balsa (Ochroma pyramidale) and Tamarind (Tamarindus indica) spheres were obtained from a wood working toy industry using knot-free wood. While Ficus spheres were all of 15 mm size, other biomass was obtained at diameters of 10, 15 and 20 mm. Cylinders of 10 and 15 mm were obtained from all the species except ficus and 10 mm cubes of pine were used in the experiments. Figure 2 shows the pictures of spheres, cylinders and cube obtained for the experiments. The temperature dependence studies involved the first four species. The densities are Ficus  $\sim 630$  kg/m<sup>3</sup>, Ivory  $\sim 630$  to 680 kg/m<sup>3</sup>, Acacia  $\sim 700$  to 750 kg/m<sup>3</sup>, Pine  $\sim$  350 to 500 kg/m<sup>3</sup>, Tamarind  $\sim$  960 to 1016 kg/m<sup>3</sup>, and Balsa  $\sim 250$  to 300 kg/m<sup>3</sup>. Experiments showed that for some samples, the density varied widely. This is considered not unusual and is thought to be related to samples over a cross section, with core showing lower density than from the peripheral region.

In each experiment, the samples were measured and weighed at two stages - before drying or heating and just before the experiment. For the experiments at 300 K, the samples were dried in the furnace at a temperature of  $105^{\circ}$ C for 24 hours and their weight was noted after cooling them in a desiccator. They were dried again in the furnace for 8 hours, cooled and weighed. If, for a given sample, there was no difference between the two weights, it was taken that the sample was dry. For the experiments with varying moisture content, the samples were dried first and then based on the dry weight the required amount of water was added to the sample to obtain the 10 % moisture. The system was allowed to equilibrate for 24 hours before the moisture was estimated by drying it and testing it as a procedure. The equivalent diameter obtained here is the average value of the diameter measured in three orthogonal directions.

For experiments at higher temperatures, the samples were kept in the

Figure 2: Samples of different species used in the experiments

furnace at the required temperature for 24 hours and experiments were conducted immediately after the sample was removed from the furnace.

Figure 3 shows the burning experimental arrangement and the photographs of wood spheres, cylinders and cubes used in this study to obtain the mass loss and gas phase temperature data. The sphere is mounted by the aid of stand and needle arrangement and it is placed on a mass balance of the least count 0.1 mg. The sphere mounting arrangement and the mass balance are separated by means of alumnio-silicate blanket of 15 mm thickness. It also shows the cylinders burning in horizontal position, vertical position and at an angle of  $45^{\circ}$ . Before starting experiment the samples mounted on the needle is sprayed with small amount of diesel fuel and it is ignited by means of a spirit lamp till 10% of weight loss of the samples, so that the sample is burning even at different experimental conditions (say sphere at 10% moisture). The mass loss of the sample is continuously measured during the burn. The time when the wood sample is fully ignited and burning on its own takes about 5 to 15 s.

Figure 3: Schematic of experimental arrangement used in the experiments to obtain mass loss vs time for spheres, cylinders and cube

A thermocouple of 0.1 mm bead size is used to obtain the flame temperature. The thermocouple was introduced into the flame and gently moved around to pick the peak temperature.

# 0.4 Results and Discussion

After several preliminary studies, 90 experiments with more than 15 for each of the species for each species were conducted. At least two experiments at each condition were conducted. Figure 4 shows typical mass vs time for several representative cases considered here. As can be noted, many curves have a near-linear variation of mass vs time over the flaming period. The slope constitutes the mass burn rate of the specific case. As can be noticed, the linear variation after a short transient is present for all the biomass over a range of

Figure 4: Select mass vs time plots showing species, size, moisture fraction and initial temperature effects

densities from 200 to 1000 kg/m<sup>3</sup>. There is a weak dependence on moisture fraction as well as initial temperature.

The ratio of the mass burn rate with initial diameter,  $\dot{m}/d_s$  from the experiments for different moisture fractions,  $f_w$  at  $T_{ini}$  = 300 K is set out in Fig. 5. As can be noted, there is sufficient variation (not scatter) between different biomass at each moisture fraction, there is a tendency for the mass burn rate to go down with moisture fraction. This is particularly so when 12 % moisture is reached. Also  $\dot{m}/d_s$  varies from about 0.5 to 0.9 g/m s over different biomass and moisture fractions up to 0.12.

Table 1: Mean values of experimental  $\dot{m}/d_s$ ,  $\dot{m}_n$  at various  $T_{ini}$ ;  $C_{\mu} = 0.562$  g/m s

Species	$\dot{m}/d_s$	$\dot{m}_n$	$\dot{m}/d_s$	$\dot{m}_n$
	at 300	0 K	at highe	er T <sub>ini</sub>

	g/m s	-	g/m s	-
Ficus	0.58	1.03	0.80	1.42
Ivory	0.60	1.06	0.78	1.39
Acacia	0.68	1.22	0.86	1.52
Pine	0.53	0.94	0.65	1.15
Tamarind	0.75	1.34	-	-
Balsa	0.60	1.06	-	-

The mean results of the burn rate data at 300 K (7 to 12 % moisture fraction) as well as at higher temperatures of 393 K, 423 K and 473 K are set out in Table 1. Across the species, there is a clear 25 % variation in the burn rate and with enhanced temperature, the burn flux increase for each species can up by 35 % from the values at ambient conditions. The largest contributor to this change is the change in B. Also, Tamarind burns the fastest while Pine, the lowest. These results are interesting and new.

The entire data set was classified according to species, moisture fraction and initial temperature. The prediction used essentially the equations 11, 12 and 13. Optimization effort consisted in minimizing the root mean square error between the predicted and the experimental values of  $\dot{m}/C_{\mu}d_s$  for each species. The root mean square error, RMSE is defined by

$$RMSE = \sum_{i=1}^{noe} \sqrt{[(\dot{m}_n, E - \dot{m}_n, P)/\dot{m}_n, E]^2}$$
(17)

where *noe* is the number of experiments for each of the samples that was 14 for Ficus, 21 for Ivory, 20 for Pine, 17 for Acacia, 11 for Tamarind and 4 for Balsa. The averages were obtained by making a choice of the heat of pyrolysis defined in eqn. 13. The results of the calculations are set out in Fig. 6.

This figure is revealing. As one varies the choice of  $H_{p0}$  for each of the sets, the error goes through a minimum as may be expected. But the nature of variation is different in the case of Ivory for which the variation is flat where as with others it is sharp. The values of  $H_{p0}$  are chosen at the lowest of RMSE for each species. The values are set out in Table 2.

Figure 5: The ratio of mass burn rate to initial sphere diameter with moisture fraction

Table 2: Values of  $H_{p0}$  for various species

Species	Ficus	Ivory	Acacia	Pine	Tamarind	Balsa
$H_{p0}$ , kJ/kg	240	210	100	$\overline{350}$	-150	150

The values differ significantly over the species. These values are connected to the combustion process directly because they are deduced from the expectation of predicting the burn rate of biomass (spheres here). It can be seen that most of the species show endothermic values for the heat of pyrolysis. It must be emphasized that this approach to determination of the heat of pyrolysis and the transfer number (to be discussed later) provide definitive estimation of these parameters.

The predictions and the experimental data for spheres are set out in Tables 3 and 4. These tables present the data on their diameter, moisture fraction,

Figure 6: The variation of the root mean square error, RMSE with the heat of pyrolysis,  $H_{p0}$ 

initial temperature at which the samples were conditioned, the density of the sphere, mass burn rate, dimensionless mass burn rate, the value of  $H_{p0}$ , the transfer number, B obtained from this correlation and the predicted dimensionless burn rate with the last column indicating the percentage error in the predictions for tests at ambient temperature and higher initial temperatures respectively. Those with errors less than 5 % can be considered very good predictions since the accuracy of the burn rate data is limited to this value. It can be noted that B is about 1 for Ficus, Ivory and Balsa, 0.8 to 0.9 for Pine, 1.1 to 1.3 for Acacia and 1.8 for Tamarind at an ambient temperature of 300 K. For higher temperatures, the values are larger going up to 2. The burn rate predictions using eqns. (11 to 13) seem to be good over the range of conditions considered.

#### 0.4.1 Burn behavior of cylinders, cubes vs spheres

Figure 7 shows the comparison of  $\dot{m}/d$  for the spheres, cylinders and cubes. It can be observed that  $\dot{m}/d$  values of cylinders burnt in horizontal position, at

Figure 7:  $\dot{m}/d$  of spheres, cylinders and cubes over several samples

angle of  $45^{\circ}$  and cubes at  $45^{\circ}$  angle are at variance from sphere and those burnt in vertical position, but cylinders and cubes burnt in vertical position are not different from those of spheres. Also visual observations showed that wooden sphere of 10 and 15 mm diameters, more particularly of 10 mm diameter burnt similar to a liquid droplets where as those of cylinder and cube had a broken flame in the top region. In view of this, it is appropriate to expect that the data from 10 mm diameter spheres can be considered the most appropriate and those from cylinders and cubes be considered of secondary importance in view of the objectives of the present study.

#### **0.4.2** Comparison with experimental data of Huff (1982)

The experimental scheme of Huff (1982) involved immersion of the cube within a jet of cold air but within a furnace operated at temperatures of 797, 1063 and 1345 K with radiant heat from the furnace being received by the cube. The author has delineated the issues that arose during the conduct of the experi-

ments and the way of rationalizing his findings. Based on this rationalization, he has provided a curve-fit of the data in terms of burn time vs size. The size is estimated by using eqn. 16. The heat from the furnace surroundings reaches the samples by radiation. The bright flame surrounding the sample would also absorb the radiation and in comparison to classical combustion arrangements, the gas temperature at the outer boundary is much higher. Thus thermodynamically, one should expect much higher flame temperatures. This is the approach taken in estimating the transfer number, B and the mass burn rate. Table 5 contains the experimental results and the choice of  $H_p$  and  $T_q$  for making the predictions. There was no simple basis for the choice of gas temperatures. What was found was that this depended on the particle size for a direct match with the experimental  $\dot{m}_n$ . Only for the highest furnace temperature case, the choice was independent of the particle size. It can be noted that the value of transfer number is as low as 0.36 and goes as high as 2.9 depending on the size and the furnace temperature. The predictions seem reasonable considering the assumptions made.

# 0.4.3 Comparison with the experiments of Momeni et al (2013)

Momeni et al (2013) conducted combustion like experiments with pine spheres and cylinders of small diameter different aspect ratio, but all with nearly same volume. The samples were burnt in an atmosphere of the combustion products of a fuel gas, presumably natural gas at near-stoichiometric conditions. The measured temperature and oxygen fraction of the hot gases are 1673 K and 0.03 to 0.04. While their experiments have dealt with ignition and char burn out conditions as well, the data of interest here is in volatile combustion rate. They have provided data on the time for conversion of various phases. They report a value of density of 600 kg/m<sup>3</sup> and use of this value leads to mass that are lower than indicated. Specifically, they indicate a mass of 0.0125 g, but the mass obtained with the density provided leads to a mass of 0.0085 g. Thus the value of 0.0085 g is retained in the analysis to follow. The scatter in the data for some cases where they have done multiple experiments is about 10 %. The predictions made here assume a flame temperature of 2200 K taking note of the fact that there is residual oxygen in the high temperature stream. The prediction procedure is the same as discussed earlier and Table 6 shows the details of the comparison of the results.

Table 6: Comparison of mass loss data of pine sphere and cylinders (Momeni, 2013), E = experiment, P = present correlation,  $\rho_{fu} = 600 \text{ kg/m}^3$ ,  $f_w = 0.09$ ,  $T_{ini} = 300 \text{ K}$ ,  $H_{po} = 208 \text{ kJ/kg}$ , <sup>a</sup> = sphere, the symbol " –" means < 5 %

#### **0.5 Procedure to estimate** *B* **for biomass**

In view of the observations in section 0.4.1, spheres as a reference geometry seem most appropriate. Biomass spheres of suitable dimensions, typically of 10 mm diameter should be produced in numbers. Samples drawn from these are conditioned at moisture levels, and dry samples should be conditioned at 0 % moisture and also at temperatures up to 423 K or thereabouts to ensure there is no loss of mass during the conditioning. The samples can then be drawn and subject to combustion experiments and the mass loss histories obtained. These are subjected an analysis to make a choice of  $H_{p0}$  minimizing the error in the prediction of mass loss rate. This process also gives the value of *B* at ambient temperature albeit within an error band. The mean value will then be the *B* for the tested biomass.

#### 0.6 Model for pyrolysis experiments

The experiments on cylinders have been conducted by Pyle and Zaror (1984) and Lu et al (2008, 2010). Unlike in classical DTA/DSC studies that use small samples of fine powder of biomass so that mass transfer limitations do not arise (like in the case of Milaosavljevic et al, 1996), the latter two studies by Pyle and Zaror as well as Lu et al aim to obtain the kinetic parameters of pyrolysis using larger sample sizes. In these cases, mass transfer can become the limiting rate criterion depending on the size and operational conditions. We will consider each of these in some detail.

The results of calculations over the full data is set out in terms of predicted vs experimental  $\dot{m}_n$  in Fig. 8. As can be noted, the dimensionless correlation seems to work very well.

#### **0.6.1** Pyle and Zaror (1984)

Pyle and Zaror have reported experimental data on a systematically designed set based on an earlier framework of Maa and Bailie (1973). Their study involved careful pyrolysis experiments on cylindrical samples of pine of diameters of 6, 15 and 22 mm and lengths between 60 and 90 mm and density between 450 and 550 kg/m<sup>3</sup>. They provide information on the conversion vs

Figure 8: Predicted vs experimental dimensionless mass burn rate (1- Ficus-Sph-373 to 423 K, 2- Ficus-Sph-300 K, 3-Pine-Sph-300 K, 4-Pine-Sph-393 to 423 K, 5- Ivory-Sph-300 K, 6- Ivory -Sph- 393 to 423 K, 7-Acacia- Sph- 300 K, 8-Acacia- Sph- 393 to 423 K, 9- Tamarind- Sph- 300 K, 10- Balsa- Sph- 300 K, 11- Mahagony- Sph- 300 K, 12- Momeni- Sph, 13-Acacia-Cyl- 300 K, 14-Acacia- Cyl- 373 K, 15- Ivory-Cyl- 300 K, 16- Ivory- Cyl- 373 K, 17- Pine- Cyl- 300 K, 18- Pine- Cyl- 373 K, 19- Mahagony- Cyl- 300 K, 20- Balsa- Cyl- 300 K, 21- Momeni- Cyl, Huff- Cubes, Sph- Sphere, Cyl- Cylinder.)

time for the samples held in a furnace at temperatures between 643 K to 780 K. The inverse of the slope of the conversion vs time curve provides the conversion time,  $t_{con}$ . This conversion time is largely that of volatiles implying the conversion of about 75 to 85 % depending on the pyrolysis temperature. The conversion vs time plots provided in the thesis of Zaror (1982) were used to obtain the conversion times for the specific cases. The actual values of lengths or density of the specific samples used are not provided in the reported experimental data. While this does not diminish the quality of the results in so far as conversion is concerned, but affects the deduction of mass loss rates during pyrolysis. In order to overcome this deficiency, a simulation exercise was conducted using random choice of both lengths and densities between these values and a mean of 6 measurements was taken to represent the properties of the actual samples used. Then, the data on mass combined with conversion times were used to get the mass burn rate.

Table 7: Comparison of mass loss data of pine cylinders (Pyne and Zaror, 1984; Zaror, 1982), E = experiment, P = present correlation,  $f_w = 0$ ,  $T_{ini} = 300$  K, the symbol " –" means < 5 %

Table 7 shows the data on these experiments. The dimensionless mass burn rate from the experiments is obtained as  $[m_{fu}/(t_{con}d_{ch}C_{\mu})]$  much like what is done for combustion experiments. For estimation of B, the "flame temperature" used is the furnace temperature,  $T_{fur}$ . The surface temperature to which heat is transferred is taken as 550 K instead of 600 K as is done for combustion studies because, the first stage of pyrolysis occurs at this condition and most transformation occurs at values around this temperature (as can be noted from the DTA-DSc results of Zaror). One can notice that the transfer number B for pyrolysis conditions of larger samples seems to be of the same order as for combustion conditions. Only for 6 mm samples, the value of B is small as may be expected. The heat of pyrolysis,  $H_{p0}$  is another parameter of choice and is indicated in the table. Pyle and Zaror indicate that their choices were either 0 or -200 kJ/kg and the results were not sensitive to it. It is not so in the present case. The conversion behavior is sensitive to the choice of  $H_p$ even though the values are in the same range as indicated above.

The experimental conversion time  $(t_{con})$  has been plotted with furnace temperature for the three diameters in Fig. 9. The left side figure shows the raw data. The lower values of the conversion time for 6 mm samples are related simply to the sizes. The dimensionless conversion time is defined as  $[t_{con}C_{\mu}/(\rho_{fu}A_s/\pi)]$ . The dependence on the fuel surface area,  $A_s$  is the same as

Figure 9: The variation of the conversion time,  $t_{con}$  and dimensionless conversion time with  $T_{fur}$ , the furnace temperature

 $d_s^2$  that appears for burn time of spheres (discussed earlier; also, see eqn. 6.1 in Mukunda, 2009). The use of  $C_{\mu}$  is consistent with the gas phase transport property dependence discussed earlier. One can notice that the use of this parameter seems very appropriate in explaining the diameter dependence as the data fall on the same curve. The burn rate variation with the furnace temperature is shown in Fig. 10. The differences in the prediction are related to the scaling used and the dependence on the transfer number B; the comparison is partly affected by the choice of unknown parameters (length and density). The B dependence approach for combustion may still be valid for pyrolysis conditions but with lesser accuracy.

Figure 10: Comparison between experimental and predicted dimensionless mass burn rate with the furnace temperature

### 0.7 Summary

In the present study, experiments on the combustion of biomass spheres of six different species and three different sizes have been conducted at various conditions of moisture fraction and for dried samples, at various conditioning temperatures below the pyrolysis temperature to evaluate the burn rate behavior and examine the possibility of extracting the transfer number B. Noting various dependences with (a) the dependence of the heat of pyrolysis on the species, and (b) the role of shrinkage influencing the effective diameter for combustion, a model was set out to describe the burn behavior in a dimensionless format.

The final correlation predicts the burn rate of all the dependences within a root mean square error of less than 8 %. The correlation has been extended to include circular and square cylinders using the square root of the surface area as the characteristic dimension. The comparison of the predictions from the correlation with the experiments of earlier researchers and those from present

experiments appears to be good.

An approach to determining the transfer number for each biomass species through the conduct of burn rate experiments on the 10 mm diameter spheres has been suggested. This procedure gives an opportunity to classify biomass like liquid fuels which have been long characterized using the transfer number. The value of B is about 1 for Ficus, Ivory and Balsa, 0.8 to 0.9 for Pine, 1.1 to 1.3 for Acacia and 1.8 for Tamarind at an ambient temperature of 300 K. It may be noted that this is new finding in the field of biomass combustion behavior.

Extension of the ideas to pyrolysis studies aimed at obtaining conversion and mass loss show the broad trends properly. The fact that the mass flux is species-dependent brings forth the need for standardization in crib fire studies relevant to fire safety testing.
